Kmeans talk – Unsupervised learning- you do not know the number of clusters or cluster membership

First: Kmeans is not KNN

K-means is a clustering algorithm that tries to partition a set of points into K sets (clusters) such that the points in each cluster tend to near each other. It is unsupervised because the points have no external classification.

K-nearest neighbors is a classification (or regression) algorithm that in order to determine the classification of a point, combines the classification of the K nearest points. It is supervised because you are trying to classify a point based on the known classification of other points.

Problems

K-means is vulnerable to outliers

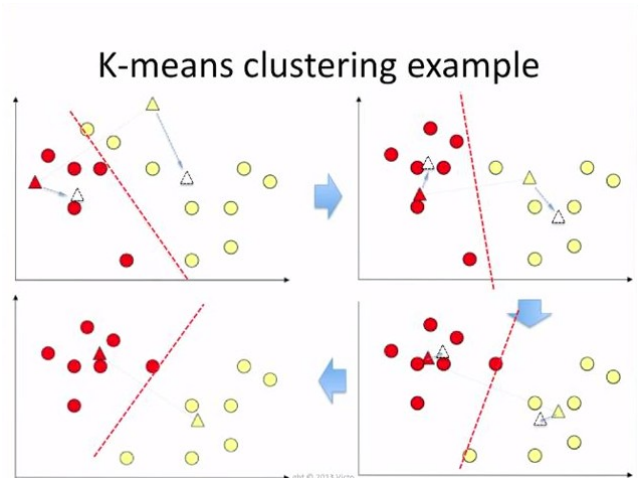
K-means works best with spherical clusters

K-means requires you to pick the number of clusters you have before you run the algorithm (how to know)

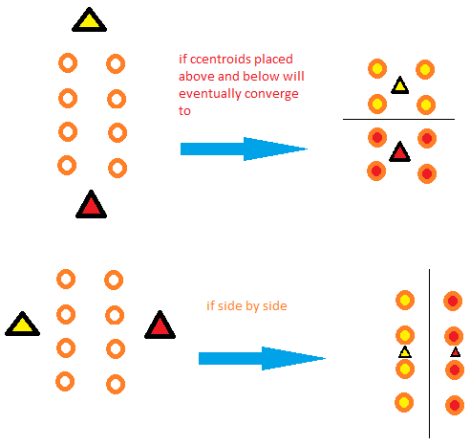
K-means is not guranteed to produce the same result every run (it depends on initial cluster centers)

Algorithm

1. Randomly pick *k* centroids from sample points as initial cluster centers
2. Assign each sample to the nearest centroid
3. Move the centroids to the center of the samples assigned to it
4. Repeat steps 2 and 3 until cluster membership stops changing



It is not guaranteed to converge to same solution every time



sklearns implementation

use kmeans++ to initialize (picks the k points in the data furthest from each other)

talk about inertia (Sum of squared distances of samples to their closest cluster center)

Pick ideal number clusters, the elbow method

calculate the inertia for every value of K, plot these inertias, look for point where K starts to increase rapidly (the elbow)

Pick ideal number clusters, the Silhouette score

Plots how tightly grouped the samples in the clusters are. How to calculate the silhouette coefficient of a single sample in a dataset. Do this for all samples then plot per cluster.

1. ai – cluster cohesion- average distance between sample and all other points in the cluster

2. bi – seperation- average distance between sample and all other points in nearest cluster

Silhouette score for point= (bi-ai)/max(bi,ai)

-1<Si<1
=0 if ai=bi then point is right on edge of being mis classified
=1 ideal bi>>ai very far away from nearest clustering
<0 then point probably misclassified

Do this for every point, then plot the scores per point and per cluster
